MINERALOGICAL CHARACTERISTICS OF THE SEPARATED MAGNETIC RUTILE OF THE EGYPTIAN BLACK SANDS

MOHAMED ISMAIL MOUSTAFA

Nuclear Materials Authority Email: ismail2251962@yahoo.com

ABSTRACT

The Egyptian black sands contain several economic minerals; the most important are ilmenite, magnetite, garnet, zircon, rutile and monazite. During the concentration and separation of a high-grade rutile concentrate, a bulk magnetic fraction was obtained and composes mainly of individual titanhematite grains, ferriilmenite-titanhematite exsolved intergrowthed grains, magnetic leucoxene, chromite and magnetic rutile. The latter represents 6 wt. % of the bulk magnetic fraction or ≈ 4 wt. % of the original rutile content in the raw sands. Most of the magnetic rutile varieties are primary rutile grains contaminated with opaque zones present as inclusions, staining-coating and/or forming with rutile composite locked grains. These rutile varieties have magnetic characters range from strong-moderate paramagnetic to very weak paramagnetic. Twenty three polished grain surfaces representing most of the magnetic rutile varieties were investigated using Cameca SX-100 electron microprobe where 193 spots were analyzed. The calculation of the average chemical composition of the identified magnetic rutile especially for TiO₂, Fe₂O₃, SiO₂, Al₂O₃, CaO and Cr₂O₃, gives 66.34%, 21.71%, 6.39%, 1.8%, 1.19%, and 0.1%, respectively. According to the obtained microprobe chemical analyses, the magnetic rutile varieties were found to consist rutile, titanhematite, pseudorutile, leached pseudorutile, and ilmenite in a decreasing order of abundance. Some inclusions were also detected in the different magnetic rutile varieties. They are composed most probably of garnet, silicon dioxide, amphibole, ilmenite, feldspar, mica and zircon. These inclusions reflect the derivation of magnetic rutile from various crystalline igneous and metamorphic rocks. The mass magnetic susceptibilities of the various investigated magnetic rutile varieties are governed by the associated mineral species and size of their corresponding zones in comparison to the rutile mineral component, in addition also to both of type and size of the associated mineral inclusions. If the content of the magnetic rutile varieties are included inside the final high grade rutile concentrate, it will affect the marketable specification and hence its salable prices. These magnetic primary rutile varieties are recommended to be blended with magnetic leucoxene or some types of the Egyptian beach ilmenite concentrates to improve their overall marketable specifications especially for both of Ti, Fe and Cr contents.

Key words:

Magnetic rutile, magnetic susceptibility, pseudorutile, titanhematite, exsolution intergrowths.

INTRODUCTION

The Egyptian black sands extend along the Mediterranean coast from Abu Qir to the west, to Rafah to the east. Most of these deposits are present now either as beach sediments or sand dunes. The east Rosetta area contains relatively enriched beach black sands. Rutile content in these beach black sands ranges from 0.05wt. % in the most upper meter to 1.5wt. % in the naturally highly concentrated surfacial beach black sands (maximum depth of 20 cm) in the eroded areas.

Many authors delt with studying the mineralogical characters of the Egyptian beach rutile e.g. El Hinnawi (1964); Kamel (1964); Zaghloul and Kamel (1966); Hammoud (1966 & 1973); The Egyptian black sand's company (1969); Dabbour (1980 & 1997); Mohamed (1987); Naim et al. (1994); Moustafa (1995 & 1999); Dewedar (1998); Bishady et al. (2004) and others.

Kamel (1964) stated that "leucoxene, ilmenite and/or hematite replacements have been recorded among some of the altered rutile grains". He explained that leucoxene commonly occurs in irregular patches in some rutile grains, while each of ilmenite or hematite is rare. Kamel (op. cit.) also explained that minute opaque iron ore crystals, zircon-like crystals and gas cavities are the different recorded inclusions in rutile grains of Rosetta black sands.

Hammoud (1973) explained that the ferriferous rutile variety represents 4.2% of the Egyptian beach rutile concentrate, and most of the particles were found to be composite in nature; displaying exsolution intergrowths and granular aggregates in polished sections. The exsolution intergrowths consist of rutile-ilmenite, rutile-hematite and rarely ilmenite-rutile. On the other hand, the granular aggregates composed mainly of rutile and ilmenite in an irregular or oriented way.

Using both of wet-gravity concentration, high-tension electrostatic separation and both low and high intensity magnetic separation techniques, most of the individual economic mineral concentrates from the Egyptian black sands can be obtained with marketable grades and accepted recoveries (Hammoud, 1966, 1973 and Moustafa, 1999, 2003 and 2007).

In the present work, 100 tons of raw sands were collected from the most top meter from an area located after 7 km to the east of Rosetta estuary (Fig. 1). Using the flowsheet shown in Fig. (2), a final high–grade rutile concentrate assaying 99.3% with an overall recovery of 88.2% was obtained in the final non–magnetic fraction (Fig. 2).

In this paper, the optimum adjustment of operating conditions for the high-intensity magnetic separator, to remove most of the magnetic rutile varieties affecting the quality of the magnetically upgraded final rutile concentrate was

predicted. Both of the chemical analysis, the identified corresponding mineral components and some of the associated inclusions were detected for 23 grains representing the various magnetic rutile varieties.

TECHNIQUES & METHODS

TECHNIQUES

Concentration and separation equipments

Utilizing the differences in physical properties between the different Egyptian economic beach minerals, the collected raw sands were processed using the following equipments: the Full size Wilfley shaking tables for wet-gravity concentration, the

Carpco (HP 167) high-tension roll-type electrostatic separator for high tension electrostatic separation, the Reading cross-belts magnetic separator, the Carpco (MIH

13-231-100) industrial high intensity induced roll magnetic separator, and the laboratory Carpco (ML H 13-111-5) high intensity lift-type magnetic separator for magnetic separation.

Microprobe analysis

The polished sections of the identified magnetic rutile varieties were examined by electron microprobe analyzer, using the Cameca SX-100 electron microprobe analyzer (EMPA), in the Institute of Mineralogy and Crystal Chemistry, Stuttgart University, Germany The microprobe instrument is equipped with three wavelength dispersive spectrometers (WDS) and an energy dispersive spectrometer (EDS). The whole surface of the polished sections was examined by

back scattered electron (BSE) images so that most of magnetic rutile grains with e.g. 10 μ m size; or even smaller could be detected. The analytical conditions were 15 kv accelerating voltage; 15nA electron current; 180S counting time for each analyzed spot in the investigated grains and a focused electron beam diameter of 1 to 4 μ m. The following standards were used: diopside for Mg and Ca, albite for Na, Corundum for Al, orthoclase for Si and K, rutile for Ti, rhodonite for Mn, Fe₂O₃ for Fe, zircon for Zr, Hf for Hf, Cr₂O₃ for Cr and sphalerite for Zn. Lines used for analysis were L α for Zr, M α for Hf and K α for each of the other analyzed elements.

Polished sections and binocular microscope were also used for investigating the studied magnetic rutile.

METHODS

The Separation of magnetic rutile varieties.

The collected raw sands which contain 0.07% rutile were screened using a 1 mm screen aperture, to remove the coarse materials (+1mm). The undersized fraction was deslimed, that the deslimed raw sands were concentrated using the available shaking tables where considerable contents of the gangue minerals including amphiboles and pyroxenes (green silicates) in addition to quartz were removed in a final tailing fraction (Fig. 2). The tabled concentrate contains 1.2% rutile and most of the other economic beach minerals. Magnetite can be removed using the low intensity magnetic drum separator. The non-magnetic fraction was treated using Reading cross-belts magnetic separator where most of ilmenite and garnet are obtained in the various magnetic fractions (Fig. 2), while both of zircon, rutile and monazite in addition to some of green silicates and remaining quartz are obtained in the non-magnetic fraction (Fig. 2). The non-magnetic fraction containing 5.8% rutile was subjected to a circuit of shaking tabling to remove the majority of the associated gangue minerals in a final tailing fraction. The obtained tabled concentrate containing 11.45% rutile, was subjected to a circuit of high-tension electrostatic separation where most of zircon and monazite are obtained in the non-conductor fraction, while most of the rutile is obtained in the final conductor fraction. Rutile represents 54.4 wt. % of that fraction. To remove most of the magnetic contaminants associated with rutile, including primary magnetic rutile varieties, individual titanhematite grains, ferriilmenitetitanhematite exsolved intergrowthed grains, magnetic leucoxene, and chromite, the conductor rutile fraction was subjected to three stages of magnetic separation using the industrial high-intensity induced roll magnetic separator. The concluded optimum adjustment of operating conditions is as follows: 10 mm air gap of the escalping magnet and 6 mm air gap for each of the second and the third magnets.

The feeding rate was one ton/hour, the used ampere was 4 and the rotor speed was 160 r.p.m. Most of the hematite and magnetic leucoxene in addition to minor rutile varieties are dominated in both of the obtained first and second magnetic fractions. The majority of magnetic rutile varieties are dominated in the obtained third magnetic fraction. The magnetic rutile varieties represent 6 wt. % of the obtained successive three magnetic fractions and \approx 4% of the original rutile content.

RESULTS AND DISCUSSION

Investigating the magnetic rutile varieties under the binocular microscope indicates that most of these grains are composed of primary rutile zones characteristic by transparent to translucent dark red, red, orange and yellow colours (Fig. 3). The grains contain small to large opaque inclusions, coatings or staining parts. Other grains seem to be composite of rutile and opaque materials (Fig. 3).

The identified mineral varieties:

Trying to differentiate between the magnetic rutile varieties, a representative sample of the bulk magnetic fraction was taken and magnetically differentiated using the laboratory lift—type high—intensity magnetic separator at a definite adjustment of operating conditions and using ampere values of 0.4, 0.8, 1.5 and 3. A representative sample of each obtained magnetic fraction was taken and the magnetic rutile varieties were picked, polished and investigated.

Six grains (G1 to G6, Fig. 4) of the 0.4 ampere magnetic fraction, eight grains (G7 to G14, Fig. 5) of the 0.8 ampere magnetic fraction, four grains (G15 to G18, Fig. 6) of the 1.5 ampere magnetic fraction and five grains (G19 to G23, Fig. 6) of the 3 ampere magnetic fraction were investigated.

The detected spots in the investigated grains were analyzed for Na_2O , K_2O , CaO, Al_2O_3 , SiO_2 , TiO_2 , MnO, MgO, Cr_2O_3 , ZnO, ZrO_2 , HfO_2 and Fe. Iron was calculated as FeO in case of the identified ilmenite spots, while it was calculated as Fe_2O_3 allover other identified cases. The obtained results are shown in Table (1) and are summarized in Table (2).

It was detected that most of the analyzed spots in the rutile mineral components are almost homogenous and composed mainly of TiO_2 (mostly more than 98% TiO_2). Minor spots have appreciable contents of Al_2O_3 or Fe_2O_3 .

The 0.4 ampere magnetic fraction:

The investigated grains are composed of rutile (G1); rutile, pseudorutile and altered ilmenite (G2); rutile and pseudorutile (G3); rutile and titanhematite including lamellae of pseudorutile and pseudobrookite (G5) and rutile and titanhematite including exsolved ferriilmenite, G6 (Fig. 4 & Table 1).

The G4 grain was identified as sphene replacing for ilmenite; containing a relatively high content of MnO, 8.2 and 7.11 Wt. % respectively (spots 21 and 22, Fig. 4 & Table 1). Mikhail (1971) explained that complete absence of either cavities or cracks between ilmenite and sphene indicates that the replacement process took place

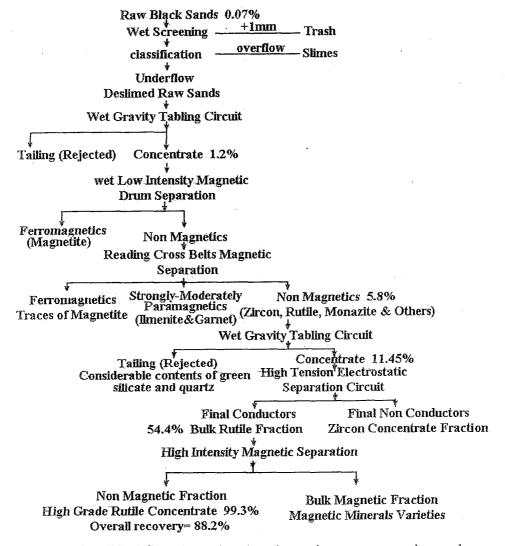

Fig. (2): A simplified flowsheet showing the various concentration and separation steps for obtaining the high-grade Egyptian beach rutile concentrate and the bulk magnetic fraction. The given percentages are corresponding to the rutile grades in each of the obtained fractions.

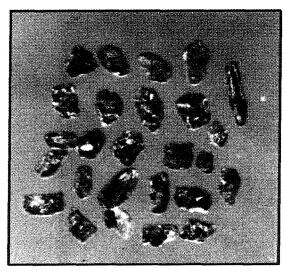

Fig. (3): Dark red, red, orange and yellow primary magnetic rutile grains associated with opaque regions of different sizes, shapes, and orientations. Binocular .microscope, X 60

volume by volume. According to Ramdohr (1940, 1956), sphene is developed by magmatic resorption or hydrothermal action.

It seems that the pseudorutile of G3 is due to rapid high temperature alteration affecting preexisting ilmenite. The reasons are almost constant chemical composition as regards to TiO2, Fe2O3, MnO and Cr2O3 and the smooth boundary betweenpseudorutile and rutile

Fig. (4): Back scattered electron images (BSE) of the investigated magnetic rutile grains from the obtained 0.4 ampere magnetic fraction.

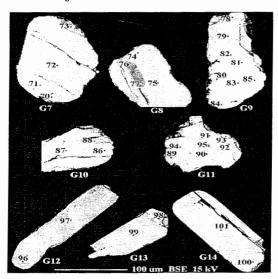

Fig. (5): Back scattered electron images (BSE) of the investigated magnetic rutile grains from the obtained 0.8 ampere magnetic fraction.

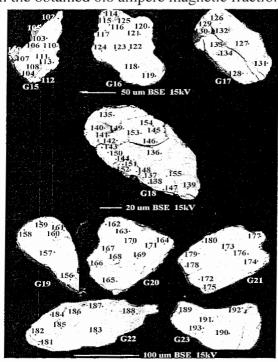

Fig. (6): Back scattered electron images (BSE) of the investigated rutile grains from the obtained 1.5 ampere magnetic fraction (G15, G16, G17 & G18), and from the obtained 3 ampere magnetic fraction (G19 to G23).

The analyzed ilmenite spot (spot 11 in G2), indicates the composition of 53.45% TiO₂, 21.33% FeO and 24.54% MnO. The remaining oxides represent only 0.3%; the total oxides equal 99.62%. The TiO₂ content is almost similar to that characteristic for ilmenite or pyrophanite. Then, the most probable mineralogical composition of the spot is a solid solution between ilmenite (FeTiO₃), and pyrophanite (MnTiO₃).

Investigating the contents of MnO% in ilmenite-pyrophanite spot (11), leached ilmenite spot (12), and the analyzed pseudorutile spots in G2 and MnO% contents in ilmenite replaced by sphene (spots 20 & 21, Fig.4 and Table 1) may indicate that ilmenite containing relatively high contents of MnO that reflects a relatively high ability for alteration.

In G5, it is obvious that the titanhematite surrounding the pseudobrookite (spot 40) shows a relatively low TiO₂ content than that surrounding the pseudorutile (spot 42, Fig. 4 and Table 1).

Balsley and Buddington (1958) and Boctor (1966) explained that in titanhematite; Fe₂O₃ with 5-10% TiO₂ as FeTiO₃ up to about 13% plus excess TiO₂ up to about 3% in solid solution. In fact, some of the analyzed titanhematite spots, in G5 and G6; have TiO₂ contents more than 10%. Therefore, the recorded ferrillmenite lamellae (Spots 68 & 69 in G6, Fig. 4) represent the unmixed excess of FeTiO₃ that present originally in solid solution with hematite. Also, the two rutile spots (50&54) in G6 (Fig. 4 and Table 1) may reflect the substitution of TiO₂ by Al₂O₃.

The 0.8 ampere magnetic fraction:

The investigated grains were identified to be composed of rutile (G7, G8, G10 and G12); rutile and titanhematite including ferriferous rutile; spots 81 and 85, (G9); rutile and ilmenite (G11) and finally individual pseudorutile prisms G13&G14 (Fig.5, Table 1).

[#] The identified inclusions.

Table (2): The investigated grains and the analyzed spots of the different identified mineral components and inclusions in the various magnetic rutile farctions.

| The type of identified inclusions | Garnet, amphibole ilmenite, feldspar, zircon | Silicon dioxide, garnef, mica | , | Silicon dioxide, garnet, feldspar | , |
|--|--|--|---|--|--|
| The identified mineral components* | Rutile,titanhematite, pseudorutile, ferriilmeinte and pseudobrookite. | Rutile, ilmenite, titanhematite and ferriferous rutile. | Rutile, individual pseudorutile | Rutile, pseudorutile, leached pseudorutile, titanhematite, ilmenite | Rutile, pseudorutile, leached pseudorutile, ilmenite |
| The number of identified inclusions | 10 | 4 | | 6 . | |
| The investigated grains and analyzed spots | (G1 to G6) From spot 1 to spot 69 | (G7 to G11) From spot 70 to spot 95 | (G12 to G14) From spot 96 to spot 101 | (G15 to G18) From spot 102 to spot 155 | (G19 to G23) From spot 156 to spot 193 |
| Description of grains | Dark red, red, orange and/or yellow rutile included, coated, stained or composited with coaque zones | Dark red, red, orange and/or yellow rutile included, coated, stained or composited with operate across | Euhedral-subhedral dark red prismatic crystals with relatively high elongation ratio. | Dark red, red, orange and/or yellow rutile included, coated, stained or composited with opaque zones | Dark red, red, orange and/or yellow rutile included, coated, stained or composited with opaque zones |
| The used current ampere | 0.4 | 0.8 | 8.0 | 1.5 | 3.0 |

* The mineral components are arranged in a decreasing order of abundance for each magnetic fraction.

The magnetic characters of the detected rutile grains that seem to be homogenous and composed completely of rutile are due to one or more of the following reasons:

- a- Magnetic inclusions of micronized sizes.
- b- Inclusions in definite crystallographic orientations other than that of the detected polished area.
- c- The deviation from the 1:2 (Ti:O) stoichiometry in synthetic rutiles, grown or heated under reducing conditions or doped with various impurities that give rise to a variety of interesting optical and electronic properties that have been extensively studied (Strawmanis et al., 1961; Johnson et al. 1968; and Khomenko et al. 1998). Such deviation in Ti:O ratio my be also affects the magnetic characters of these rutiles.

On the other hand, the two detected prismatic crystals of individual pseudorutile (G13 & G14) seem to be of primary origin. They have characteristic chemical contents where Al_2O_3 are 1.25 and 1.72%, MgO are 6.51 and 7.23%, and Cr_2O_3 are 0.48 and 0.96%, respectively. Also, relatively greater sum total oxide contents (97.81 and 99.24%) in addition to the euhedral -subhedral crystal habits.

The 1.5 ampere magnetic fraction:

The identified grains were composed of rutile and titanhematite that including exsolved ilmenite lamellae (G15), rutile and pseudorutile (G16); rutile and ilmenite (G17), and rutile, pseudorutile and leached pseudorutile; G18 (Fig. 6 & Tables 1,2). In these cases, the analyzed spots of pseudorutile seem to be of secondary origin after ilmenite. The reason is the relatively lower sum of total oxides and the characteristic MnO contents which are similar to those detected within the analyzed spots of the associated identified ilmenite (spots 129&131 in G 17, Fig. 6).

According to Temple (1966), the oxidation and partial removal of iron from ilmenite lattice results in the formation of pseudorutile which contains (65-70%) TiO₂ at the complete oxidation stage of the original iron in the ilmenite.

Gevorkyan and Tananayev (1964), explained that within the pseudorutile composition range (60-71% TiO_2), the water content increased from ~ 2 to 4.5 wt.% with decreasing iron oxide content. They proposed that the intermediate alteration phases comprise mixtures of TiO_2 with iron hydroxides. On the other hand, Gery et al. (1994) stated that pseudorutile Fe_2^{3+} Ti_3O_9 has recently been

revalidated as a mineral species with a hexagonal primitive unit cell. It is formed due to the alteration of ilmenite by the removal of Fe²⁺. The electrostatic charge balance is maintained by oxidation of the remaining iron to Fe³⁺ and/or the addition of H⁺. If the Fe²⁺ is removed in any regular pattern, then the pseudorutile will show ordering.

Frost et al., (1983), explained that pseudorutile may be an oxyhydroxide mineral with an extended range of homogeneity due to replacement of Fe^{3+} by $3H^+$ giving the general formula Fe_{2-x}^{3+} Ti_3O_{9-3x} (OH) $_{3x}$. Chernet (1999) and Chernet and Pakkanen (2003), identified the alteration product, which deviates substantially from the ideal ilmenite composition but not completely altered to pseudorutile, as leached ilmenite. Further alteration of pseudorutile to leucoxene often shows an intermediate product identified as leached pseudorutile. Along with the advance of the alteration, the water content increases until the breakdown of a pseudorutile structure, which appears at the composition of about (77 – 79%) TiO_2 and (9-12%) Fe_2O_3 ; the remaining percentage is mostly H_2O molecules (Chernet, 1999).

In fact, all the analyzed spots of pseudorutile and leached pseudorutile are in agreement with most of the forementioned published results. The depletion of the sum of the total oxides (from 92.34-94.36 % for spots 149-155, G18), is due to the presence of water molecules which are corresponding to the added hydroxyl ions due to ilmenite alteration into pseudorutile and/or leached pseudorutile. The contents of MnO% in ilmenite and leached ilmenite in G17 and for pseudorutile and leached pseudorutile in G18 (see Fig. 6 and Table 1) may indicate the high alteration ability of ilmenite containing relatively high contents of MnO.

Also, the analyzed leached pseudorutile spots; 149 to 155, in G18 (Fig. 6 and Table 1), may reflect the role of SiO₂, Al₂O₃ and/or CaO in the process of ilmenite alteration.

The 3 ampere magnetic fraction:

The identified grains were composed of rutile and pseudorutile (G19); rutile and pseudorutile with relics of preexisting ilmenite (G20); rutile and ilmenite (G21); rutile and leached pseudorutile (G22) in addition to rutile with leached ilmenite, leached pseudorutile and ilmenite; G23 (Fig. 6, Tables 1,2).

In these cases, the pseudoruitle and leached pseudorutile are considered to be secondary in origin due to the alteration of preexisting ilmenite. Also, their chemical analyses are confirmed with the concepts of Chernet (1999) and Chernet and Pakkanen (2003). The contents of MnO% for ilmenite and leached ilmenite in

G21 and for leached ilmenite, pseudorutile and leached pseudorutile in G23 (see Fig. 6 and Table 1) may ensure that ilmenite containing relatively high contents of MnO has relatively high ability for alteration into leached ilmenite, pseudorutile followed by leached pseudorutile, which has the lowest MnO% content.

It was noticed that for only the intermediate alteration product defined as leached pseudorutile (spots 184-188 in G22, Fig. 6 and Table 1), the contents of SiO₂, Al₂O₃ and/or CaO are relatively high. This may reflect the role of one or more of these oxides in the later stages of pseudorutile alteration to give the relatively enriched TiO₂ alteration products.

3.2 The identified inclusions

Several inclusions were detected in the various rutile grains. They include garnet, silicon dioxide, amphibole, ilmenite, feldspar, mica and zircon. These inclusions reflect the derivation of the studied magnetic rutile from different crystalline igneous and metamorphic rocks.

3.3 The magnetic characters of the studied rutile varieties.

Concerning with the mass magnetic susceptibilities of the various investigated rutile varieties, it can be concluded that both of the associated mineral component species and their corresponding sizes in relation to the associated rutile mineral component, govern the magnetic behaviour of these grains. The type and size of the associated inclusions are also considered another important factor affecting the magnetic behaviour of the grains. It is obvious that the rutile grains contain relatively high content of titanhematite, that may contain considerable contents of dissolved TiO₂ and definite inclusion species of ilmenite, garnet and/or amphibole (G5 & G6, Fig. 4), have relatively high mass magnetic susceptibilities. It is clear that rutile grains containing for small parts of ilmenite (G11, Fig. 5), or have titanhematite of relatively lower dissolved TiO₂ contents (G9, Fig. 5), and do not contain appreciable parts of magnetic inclusions, have moderate magnetic characters as the identified individual pseudorutile grains (G 13 & G14, Fig. 5).

The grains containing for relatively low contents of titanhematite (G15, Fig. 6), or ilmenite (G 17, Fig. 6), and/or relatively low contents of pseudorutile (G16 & G18, Fig. 6), have weak magnetic characters. On the other hand, the grains of much low contents of pseudorutile, ilmenite and/or contain only leached pseudorutile (G19, G20, G21, G22 & G23, Fig. 6), have the lowest magnetic characters.

3.4 The quality of the Egyptian beach high-grade rutile concentrate.

The high grade rutile concentrate contains more than 97% TiO₂ and most of the other analyzed minor oxides are within the accepted limits of marketable specification (Hammoud 1966 & 1973 and Moustafa, 1999). Neglecting the identified mineral inclusions in the studied magnetic rutile varieties and calculating the average chemical composition of the other analyzed spots, the following contents are obtained: TiO₂, 66.34%, Fe₂O₃, 21.71%; SiO₂, 6.39%; Al₂O₃, 1.8%; CaO, 1.19% and Cr₂O₃, 0.10%. Then, if the magnetic rutile varieties are included within the high – grade rutile concentrate, it may affect the marketable specification of the concentrate. It is recommended to blend these magnetic rutile varieties with magnetic leucoxene or with definite amounts of some types of the Egyptain ilmenite concentrates to improve the marketable specification especially for Ti, Fe and Cr.

CONCLUSIONS

During the concentration and separation of the Egyptian beach high-grade rutile concentrate, some magnetic rutile varieties are contained in the final obtained magnetic fractions. These varieties represent about 4% of the original rutile content in the raw sands.

The identification of the different magnetic rutile varieties; using electron microprobe analyses revealed the following mineral components in a decreasing order of abundance: rutile, titanhematite, pseudorutile, leached pseudorutile and ilmenite in addition to the existance of individual pseudorutile crystals which are most probably of primary origin.

It was concluded that the ilmenite which contains high MnO contents has more ability for alteration into other mineral components characterized by relatively low MnO contents.

Both of SiO₂, Al₂O₃ and/or CaO may play important roles in ilmenite alteration process, especially in the final stages of alteration (e.g. leached pseudorutile).

Several mineral inclusions are detected; they are composed most probably of garnet, silicon dioxide, amphibole, ilmenite, feldspar, mica and zircon. The identified inclusions may reflect the derivation of the magnetic rutile varieties from various crystalline igneous and metamorphic rocks.

The mass magnetic susceptibilities of the different magnetic rutile varieties are governed by the types and amount of the associated mineral components, in addition to the type and size of contained inclusions.

It is difficult to liberate the different mineral components; and inclusions, associated with rutile using grinding followed by various ore dressing techniques. Then, the removal of these magnetic rutile mineral varieties improve the quality of the obtained high-grade rutile concentrate. These varieties can be blended with definite amounts of magnetic leucoxene or some types of ilmenite concentrates to improve their marketable specifications especially for Ti, Fe, and Cr.
